      STATISTICAL KODELS
      Focus on RECRESSION HODERS: study the relationship between vouldbles
      The role of the voriables is asymmetric: there one 2 types of voriables:
          · RESPONSE / DEPENDENT voicoble y
          · one or more PREDICTORS/COVARIATES/INDEPENDENT voicibles X1, X2, ..., Xp
      God of repression models: study how the response von. is influenced by the predictors
      Examples: - evaluate how the blood pressure (7) is affected by a specific treatment (x1),
                     while also controlling for the individual characteristics (x_2 = age, x_3 = weight,...)
                  - predict the number of claims (y) given the insurer's characteristics (age, past accidents,...)
         ⇒ y = g (x1, ..., xp)
                     our good is to study g(.)
      As usual, the voilables are observed an several individuals / statistical units
         n = number of opervations
       we only consider 1 response voicible y
       The number of predictors is P>1.
       The date are organized into a matrix: rows - individuals
                                                    columns -> vouisbles
                                           1 95
                                                                                  P-th
                         response.
                                                        2rd
          statistical
                                         predictor
                                                       predictor
                                                                                 prediction
                         voriable
                                           X21
                                                          X22
                                                                                                 the submatrix of the coveriates
                                                           Xiz
                                            Χi
                                                                                     Xip
                                                           Xu2
                                                                                     Xup
                                            Xn1
                                                                                                   is called the "model matrix"
      When do we need statistics? In the applications we consider, the value of the response variables is not fully
      determined, given the values of the covoriates -> there is uncortainty
      The relationship between y and (X1,..., Xp) is stochastic.
      STATISTICAL MODELS: We assume that the observations ove REACIZATIONS of RANDOM VARIABLES
       => we study how the distrebution of the response variable depends on the values of the covariables
           ⇒ Y ~ f(y ; ×1,..., xp)
      · common assumption; the covorietes one non-stochastic and measured without error.
        this is justified in experimental settings (e.g. I fix the dose of the treatment and study the outcome).
        In observational studies this is charly not possible (e.g. demographic/economic/soubl studies).
         For simplicity, the hypothesis is mainteined, with the interpretation that the analysis is performed
         conditionally on the observed values of the covariates (i.e. Yi | X_1 = x_1, ..., X_p = x_p \sim f(y; x_1,...,x_p))
       How do we actually build a model and perform the analysis?
       The Fundangental Steps:
          4) HODEL SPECIFICATION
                 given the good of the study and the available data, specify the model (also using past info, theories on the problem,...)
          2) ESTINATATION
                estimate the model parameters (unknown quantities that define g()) on the basis of the observed data
           3) HODEL CHECKING / DIAGNOSTIC
                are the hypothesis undereging the model coherent with the observed data? Yes: use the model
                                                                                                no: go back to 1) and repeat
        HODEL SPECIFICATION
      1A. The RANDOH COMPONENT
       The type of model that we specify mainly depends on the nature of the response voilable
         ( since we are modeling the distribution of Y)
         RESPONSE VARIABLE
         • OUANTITATIVE \frac{1}{2} continuous (support IR) \rightarrow Gaussian linear model; linear model via OLS (no Gaussian assumption) \frac{1}{2} discrete / counts (support INo) \rightarrow Paisson regression (GLH)
         nominal variables

(no order in the levels)

(only 2 levels, e.g. presence/absence)

more than 2 categories, not ordered -> Logistic regression / multinomial model (GLK)
                                                                                              → Logistic regression (Copit model), probit model (GLH)
                            ordinal variables
                            (the categories have an intrinsic ordering, e.g. rankings law/medium/high _> Cumulative Cogit/probit model (GLK)
                                       notes very unsorisfied / unsorisfied / sorisfied / very sorisfied )
      The type of response variable drives the choice of the distribution f(y_i x_{x_1...,x_p}).
      1B. The RELATIONSHIP between Y and X4,... (Xp: g(.)
        it is deterministic: it is also called the SYSTEMFTIC COMPONENT
        we will consider the case where q(·) is completely specified by a FINTTE set of (unknown) REAL PARAMETERS 36 @ S R3, 9>1 finite.
        The specific way each covariate enters the model depends on the type of variable (mar details later...)
 2 ESTIMATE
    The estimate procedure consists in estimating the unknown parameters on the basis of the observed data.
    Once we estimate o, the relationship between Y and x4,...,xp is completely known.
 3 HODEL CHECKING
      Howing uniquely defined the model, we need to check:
       · goodness of fit: does the model fit the observed date well?
       · do we need all the considered covariates or a more parsimonious model can be defined (without this of fit)?
       . are the distributive assumptions satisfied?
    If the model checking highlights some kind of problem, we have to go back to the model specification (and change,
      for example, the way the variables enter the model, the number of covariates, the assumptions on the law f)
     and repeat the procedure until step 3 gives good results.
    Then, the modul can be used for:
    - inference on the parameters: understand the effect of each covariate
    - prediction: given specific values of the conscients, what is the value of Y? (coreful with prediction at values of the X; outside
           of the observed range ie extrapolation)
 So for, we have denoted the relationship between Y and (x1,...,xp) simply as Ynf(y; x2...,xp)
 meaning that the distribution of Y depends on the constitutes.
assumption 1:
 regression hobel
 We model the conditional expectation of Y given xx,..., xp
   IE[Y|x_{1},...,x_{p}] = q(x_{2},...,x_{p})
assumption 2:
  ADDITIVE ERROR TERM
  The simplest way to introduce the stochastic component is to consider
              QUELLE PROCESSION STOCHASTIC
    (notice: GLHs alo not fall into this kind of specification)
   Repression models can be classified based on:
   1. the number of voriables involved
   2. the type of function einking Y to the x_j, j=1,...,P
    (1) NUMBER OF VARIABLES
    10. number of INDEPENDENT voviables:
           • "SIMPLE" regression: only 1 covariate Y = g(x_1) + \delta
           · "HULTIPLE" regression: P>1 covoliales Y= g(xx,..., xp)+E
    16. number of DEPENDENT voiables:

    univariate: only 1 response Y

           · multivouate: the response is a vector \underline{Y} = (Y_{2}, ..., Y_{m})
      2) TYPE OF FUNCTION g(·)
      2a. PARAMETRIC: g can be expressed using a FINITE number
           of parameters 9:(\theta_1,...,\theta_q)\in\Theta^q\subseteq\mathbb{R}^q, q finite
          - LINEAR: 9(.) is a parametric function and it is UNTAR in the parameters
              We denote the parameters with B, hence
                             9 (xs,..., xp) = P1 x1+ B2x2 + ... + Bxp
```

(e.g. kernel regression, thees, RF, speines, nearest neighbors,...)

CIP regression

In the following, we will focus on linear regression kodess with an adalitive error term.

We start with SIKPLE einear regression, and then move to kultiple regression.

Examples: $g(x) = \beta_1 x$

Example: $Y = \frac{P_1 X}{B_{21} + X} + \varepsilon$

8(x)= B1x + Bx x3 + Bx3

q(x1, x2, x3) = \beta_1 x1 + \beta_2 coq x4 + \beta_3 e^{x_1 + x_3}

But if we take the logarithm: $e^{x} = e^{x} + e^{x}$

-> NON-LINEAR: it is parametric but it is not linear nor cinearitable

26. NONPARAHETRIC: the parameter space @ is not a subset of 127

Notice that the voribbles x; need not be einear! We can transform them to better fit the data.

 \Rightarrow $\gamma = \beta_1 + \beta_2 \cdot \chi + \xi$ einear

- "LINEARIZABLE": the relation is not linear, but there is a tronsformation to make it so:

9(x)= 12 Copx - By 1x

the parameters $\beta = (\beta_2, \beta_2, \beta_3)$ enter einearly.

Example: the model $Y = \beta_1 \cdot x^{\beta_2} \cdot \xi$ is not linear.
